The present analysis for the spherical nebula reduces in the limit to Chandrasekhar's corresponding analysis for the plane nebula.¹ Allowing for the dilution factor, the difference between the fluxes in L_α for the moving and the static nebula is found to be a constant, as in the plane case. The two constants are, however, different, and are equal only in the limiting case when the sphere reduces to a plane.

Struve, Otto. The spectrum of the cluster-type variable CY Aquarii.

The cluster-type variable CY Aquarii has the shortest period among the 10,912 variables listed in the recent catalogue by Kukarkin and Parenago. It is only 88 minutes or 0.061038476 day. Gossner and Ashbrook¹ have found that the period is probably variable but the above value determined by Wesselink is sufficiently accurate for our purpose. The brightness changes between 10.5 and 11.4 on the photographic scale. Hence, it was necessary to use a spectrograph of relatively small dispersion in order to make the exposure times short enough. With the Cassegrain spectrograph of the McDonald Observatory equipped with two quartz prisms and a Schmidt camera of 180 mm focal length the linear dispersion is 100 Å/mm at $\lambda 3933$. With this dispersion the exposure times for well broadened spectrograms range between about 10 minutes at maximum light and 24 minutes at minimum light. The hydrogen lines are strong at maximum and the spectrum does not look abnormal but near minimum light the hydrogen lines are weak as compared to the line of $Ca II$ 3933 and the metallic lines, though weakly present, are not as strong as one would expect. Radial velocities have been determined from 11 members of the Balmer series and from the line $Ca II$ 3933. The results are shown in Figure 1. Phase zero corresponds

to maximum light. The radial velocity is then at its lowest value, namely about -64 km/sec. The maximum radial velocity of about 0 km/sec is reached at about phase 0.75 which corresponds approximately to the minimum of the light curve. The total range is of the order of 64 km/sec which is very nearly the same as that observed in RR Lyrae and XZ Cygni. There is thus no conspicuous relation between the amplitude of the velocity curve and the period. It should also be pointed out that among the cluster-type variables there is no pronounced relation between median spectral type and period as there is among the classical Cepheids. The average spectral type of CY Aquarii is only very slightly earlier than that of RR Lyrae and XZ Cygni and is not as early as was believed by Wachmann who had tentatively announced a variation from B8 to A3. The average radial velocity of the variable is about -32 km/sec.

Thomas, R. N. On emission lines at high kinetic temperature.

If one admits the existence of a general outer stellar atmosphere whose kinetic temperature exceeds the radiation temperature of the star, some other mode of energy transfer than radiation is implied. There exists thus the possibility of increasing the emission in certain spectral regions without requiring a diminution in others. The conditions for a net chromospheric emission under conditions of high kinetic temperature and non-thermodynamic equilibrium are presented, with results in general considerably different from the earlier conclusions of Menzel. The most pressing refinement needed for the general case over the type calculations already made for the solar chromosphere, where Lyman emission and Balmer absorption were found, lies in the consideration of collisional excitation from the $n = 2$ level. The inclusion of such a term may force the earlier Balmer members into emission under conditions of sufficiently large electron density and kinetic temperature. It is suggested that the phenomenon may find application in the transitory bright line spectrum observed by Struve in RR Lyrae.
